Abstract

Background

The coronavirus disease 2019 (COVID-19) is a newly recognized illness that has spread rapidly all over the world. Severe hypoxemic respiratory failure from COVID-19 will bring high risk of venous thromboembolism (VTE). Our study aims to identify in-hospital VTE risk and bleeding risk in COVID-19 patients.

Methods

We retrospectively studied 138 consecutively enrolled patients with COVID-19 and identified in-hospital VTE and bleeding risk by Padua Prediction Score and Improve bleed risk assessment model. The clinical data and features were analyzed in VTE patients.

Results

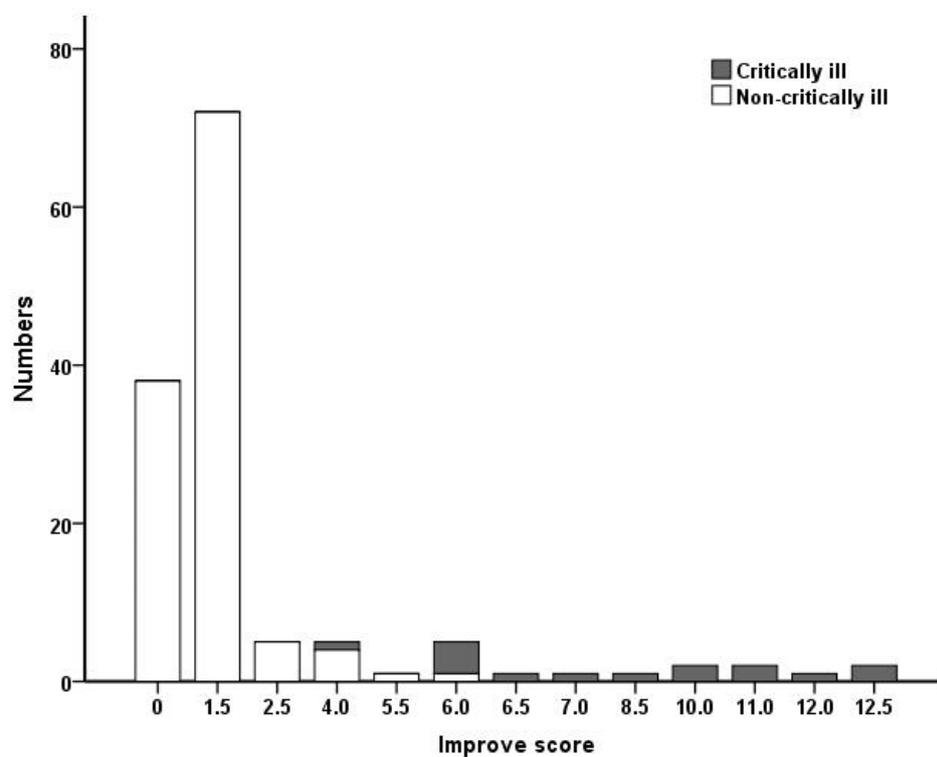

Our findings identified that 23 (16.67%) patients with COVID-19 were at high risk for VTE according to Padua prediction score, and 9(6.52%) patients were at high risk of bleeding for VTE prophylaxis according to Improve prediction score. Fifteen critically ill patients faced double high risk from thrombosis (Padua score more than 4 points in all 15[100%] patients) and hemorrhage (Improve score more than 7 points in 9[60.0%] patients). Thrombotic events were identified in four patients (2.9%) of all COVID-19 patients. All of them were diagnosed as deep vein thrombosis by ultrasound after 3 to 18 days after admission. Three (75.0%) were critically ill patients, which means the incidence of VTE among critically ill

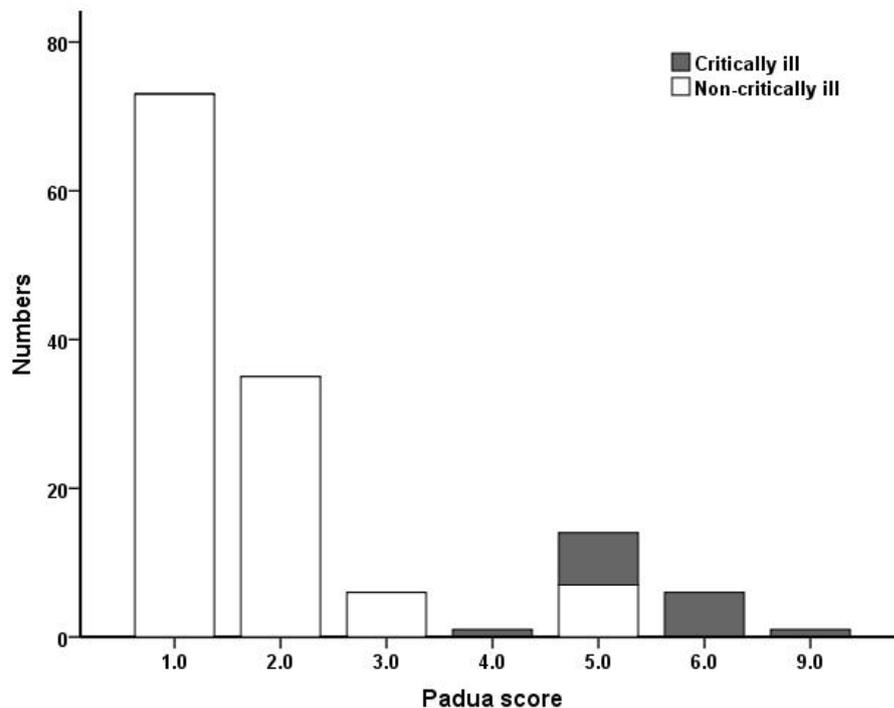

patients was 20%. One major hemorrhage was happened in critically ill patients during VTE treatment.

Conclusion

Critically ill patients with COVID-19 suffered both high risk of thrombosis and bleeding risks. More effective VTE prevention strategies based on an individual assessment of bleeding risks were necessary for critically ill patients with COVID-19.

Figures

Background

The coronavirus disease 2019 (COVID-19) is a newly recognized illness that has spread rapidly throughout Wuhan (Hubei province) to other provinces in China and around the world (1–4). The clinical spectrum of COVID-19 ranges from mild to critically ill cases. Previous studies have mentioned old age, and those with coexisting medical conditions were more likely to have a poor prognosis (5). These factors, as well as infection, bedridden, and respiratory failure, are all risk factors for venous thromboembolism (VTE) (6, 7). Once COVID-19 complicated with deep vein thrombosis (DVT) or fatal pulmonary thromboembolism (PTE), the treatment will be challenging, and patients with VTE may have a worse clinical outcome.

In this study, we assessed the risk of VTE and bleeding and compared the risks between critically ill patients and those of non-critically ill in hospitalized patients with COVID-19 from the Shanghai Public Health Clinical Center. We also report our experience with four patients that suffered clinically striking thrombotic events with COVID-19.

Methods

Study Design And Participants

This single-center, retrospective, observational study was done at Shanghai Public Health Clinical Center (Shanghai, China), which is a designated hospital to treat patients with COVID-19. We retrospectively analyzed patients from Jan 21, 2020, to Feb 21, 2020, who had been diagnosed with COVID-19, according to WHO interim guidance(8). Laboratory confirmation of COVID-19 infection was performed by the local health authority(1, 2). Critically ill patients were defined as those admitted to the intensive care unit (ICU) who required mechanical ventilation or had a fraction of inspired oxygen (FiO₂) of at least 60% or more(9). Identification of critically ill patients was achieved by reviewing and analyzing admission logs and histories from all available electronic medical records and patient care resources. The Ethics Commission of Shanghai Public Health Clinical Center approved this study. Written informed consent was waived due to the rapid emergence of this infectious disease.

Data Collection And Definition Of Terms

Variables that were collected from the patients' electronic medical records and completed from the medical files included; demographic, anthropometric, and clinical variables that are components of the Padua prediction score and Improve bleeding risk prediction score.

The Padua prediction score was calculated, for each patient at study entry, according to the weight and number of the following risk factors; active cancer (3 point), previous VTE (3 point), reduced mobility (3 point), already known thrombophilic condition (3 points), recent (\leq month) trauma and/or surgery (2 points), elderly age (\geq 70 years) (1 point), heart and/or respiratory failure (1 point), acute myocardial infarction or ischemic stroke (1 point), acute infection and/or rheumatologic disorder (1 point), ongoing hormonal therapy (1 point), and obesity (BMI \geq 30 Kg/m²) (1 point). A high risk of VTE is defined as a cumulative score \geq 4 and a low risk as one of $<$ 4(10).

The Improve bleeding risk prediction score was calculated according to the weight and number of the following risk factors; active gastroduodenal ulcer (4.5 points), bleeding within past 3 month (4 points), admission platelets $<$ 50×10^9 cells/L (4 points), hepatic failure (2.5 points), ICU/CCU stay (2.5 points), central venous Cather(2 points), rheumatic disease(2 points), active malignancy(2 points), age 40–80 (1.5 points), age \geq 85(3.5 points), renal disease: Glomerular filtration rate (GFR) 30–59 ml/min (1 points), GFR $<$ 30 ml/min (2.5 points). A high risk of Bleeding is defined as a cumulative score \geq 7 and a low risk as one of $<$ 7(11).

Routine thromboprophylaxis was provided to patients whose Padua score more than four points. For those with Improve score more than 7, intermittent pneumatic compression (IPC) or low intensive thromboprophylaxis was suggested. Lower extremity compression ultrasound (CUS) was performed for all critically ill patients and those with high risk of VTE and high level of D-dimer. If possible, these patients received computed tomography pulmonary angiogram (CTPA). VTE and bleeding complications and their management were recorded.

Statistical Analysis

Statistical calculations were done with the software package Statistical Package for the Social Sciences version 21 (IBM SPSS Statistics; Armonk, NY, USA). We expressed descriptive data as mean (standard deviation) or median (interquartile range) for continuous variables and number (%) for categorical variables. We assessed differences between critically ill patients and non-critically ill ones using two-sample t test or Wilcoxon rank-sum test depending on parametric or nonparametric data for continuous variables and Fisher's exact test for categorical variables. Tests were two-sided with significance set at α less than 0.05.

Results

Demographic And Clinical Characteristics

The study population included 138 hospitalized patients with confirmed COVID-19 in Shanghai Public Health Clinical Center, of whom 15 (10.9%) were critically ill. 81 (58.7%) patients were male. The average age was 52.43 ± 16.68 years. Of the 138 patients, 56 (40.6%) had 1 or more coexisting medical conditions. Hypertension (39 [28.3%]) and diabetes (16 [11.6%]) were the most common coexisting conditions. Compared non-critically ill patients ($n = 123$), critically ill patients were significantly older (60.07 ± 14.25 years vs 50.52 ± 15.97 years; $P < 0.01$) and were more likely to have underlying comorbidities, including atrial fibrillation (3 [20.0%] vs 3 [2.4%]), hypertension (8 [53.3%] vs 31 [25.2%]), and stroke (4 [26.67%] vs 0 [0%]). Furthermore, critically ill patients had abnormally elevated D-dimer levels on baseline, which was significantly higher than non-critically ill patients ($0.74[0.44,135]$ vs $0.39[0.29,0.83]$, $P < 0.01$). There were no significant differences in gender, weight, and other complications between critically ill and non-critically ill patients.

Risk Prediction Of VTE In COVID-19

Padua score in COVID-19 patients ranged from 1 point to 9 points and the median risk score was 1 point. Overall 115 (83.3%) patients had Padua score < 4 (low risk for VTE), and 23 (16.7%) patients had Padua score ≥ 4 (high risk for VTE). The presence of high risk for VTE was more common among patients with critically ill than those with non-critically ill patients (15[100%] vs 7[6.5], $P < 0.01$),

as illustrated in Table 1 and Fig. 1. The most common Padua risk parameters involved in COVID-19 were acute infection (138[100%]), heart failure or respiratory failure (55[39.9%]), reduced mobility (21[15.2%]), and elderly age (17[12.3%]). Compared non-critically ill patients, critically ill patients were more likely to have the following VTE risk factors, including reduced mobility(15[100.0%] vs 6[5.0%], P < 0.001), elderly age (7[46.7%] vs 10[8.3%], P < 0.001), respiratory failure (11[73.3] vs 44[36.4%], P < 0.01) and obesity (2[13.3%] vs 0[0%], P = 0.01), as shown in Table 2. All patients at high VTE risk received adequate prophylaxis.

Bleeding Risk Prediction For VTE Prophylaxis In COVID-19

Improve score in COVID-19 patients ranged from 0 point to 12.5 points and the median risk score was 1.5 point. Overall, 129 (93.5%) patients had Improve score < 7 (low risk for bleeding), and 9 (6.5%) patients had Improve score \geq 7 (high risk for bleeding). The presence of high risk for bleeding was obviously more common among patients with critically ill than those with non-critically ill patients (9[60.0%] vs 0[0%], $P < 0.01$), as illustrated in Table 1 and Fig. 2. The most common Improve risk parameters involved in COVID-19 were age between 40 and 84 years (95[68.8%]), ICU stay (15[10.9%]), and central venous catheter (14[10.1%]). Compared non-critically ill patients, critically ill patients were more likely to have the following bleeding risk factors, including bleeding with past 3 months(5[33.3%] vs 1[0.8%], $P < 0.001$), hepatic failure(3[20.0%] vs 2[1.6%], $P = 0.011$), ICU stay(15[100.0%] vs 0[0%], $P < 0.001$), central venous catheter(13[86.7%] vs 1[0.8%], $P < 0.001$), age between 40 and 84 years(14[93.3%] vs 81[65.9%], $P = 0.023$), and GFR less than 30 mL/min(2[13.3%] vs 0[0%], $P = 0.011$). For patients both at high risk for VTE and bleeding, most patients accepted low-dose heparin or low molecular weight heparin (LMWH) and 2 patients applied IPC. A total of 6 (4.3%) patients who were all at high bleeding

risk experienced bleeding event, including mild hematuria or microscopic hematuria (3[2.2%]), mild gastrointestinal bleeding (1[0.7%]), moderate nosebleed (1[0.7%]), and severe hemothorax (1[0.7%]).

Thrombotic Complications In COVID-19

Thrombotic events were identified in four patients (2.9%) of all COVID-19 patients. All of them were diagnosed as DVT by ultrasound on the 3rd to 18th day of admission. Three (75.0%) were critically ill patients, which means the incidence of VTE among critically ill patients was up to 20%. All four patients were male whose ages ranged from 25 to 70 years and had one or more coexisting medical conditions. Baseline D-dimer elevated, but to varying degrees in three patients. The other patient had a normal D-dimer level on the baseline which increase to 3.9 µg/ml at 14 days after admission. Three of these patients received mechanical ventilation and central venous catheter treatment; one of whom used continuous renal replacement therapies (CRRT); and one had extracorporeal membrane oxygenation (ECMO) treatment. All patients accepted anticoagulant therapy with LMWH or heparin. One patient with a high risk of bleeding had severe hemothorax. All patients survived except one died of respiration failure (Table 4).

| | Patient 2 | Patient 3 | Patient 4 | |

Discussion

Our findings identified that 16.67% of patients with COVID-19 were at high risk for VTE according to Padua prediction score, and 6.52% of patients were at high risk of bleeding for VTE prophylaxis according to Improve prediction score. The prediction risk of VTE (6.5%), as well as the incidence of VTE (0.8%), was low in non-critically patients. However, critically ill patients faced double high risk from thrombosis (Padua score more than 4 points in 100% of critically ill patients) and hemorrhage (Improve score more than 7 points in 60.0% of critically ill patients). Furthermore, we identified a high incidence of VTE (20.0%) in critically ill patients with COVID-19, despite the use of universal, guideline-recommended thromboprophylaxis. Critically ill patients suffered a marked incidence of bleeding (26.7%), which suggested a complicated situation in VTE prophylaxis to COVID-19.

As described, there are several reasons for high risk of VTE in critically ill patients with COVID-19. On the one hand, critically ill population in our findings had three qualities in physiology, including: venous stasis due to sedation or bedridden, hypercoagulability caused by glucocorticoid and immunoglobulins, and endothelial damage from central venous catheterization and/or ECMO. On the other hand, a significant number of COVID-19 patients, especially critically ill ones, were the aged(1) who were easy to complicate with VTE high risk factors, such as heart failure, stroke, cancer and diabetes. In addition, critically ill patients had a higher level of D-dimer compared to non-critically one(5), which might be associated with hypercoagulability induced by coronavirus. All these factors increased the risk of developing potentially deadly blood clots.

The COVID-19 patients, especially critically ill ones, should pay attention to high risk of bleeding during thromboprophylaxis. Older Age is the high-risk factors of both thrombosis and hemorrhage(11, 12). Nearly 70% of patients in our study had age-related bleeding risk. Besides age, coexisting medical conditions, including tumors, renal or liver failure, hypertension, and diabetes, brought the risk of bleeding in our patients. Moreover, some Invasive treatment increased the bleeding risk, especially ECMO which widely used in critically ill patients(13). Our findings confirmed four patients with VTE complications. That did not mean the rate of VTE complications occurring in COVID-19 patients was low. More likely, it was the consequence of effective thromboprophylaxis in patients classified as being at high risk of thrombosis. The high incidence of VTE in critically ill patients of COVID-19 despite the universal use of guideline-recommended VTE prophylaxis was similar to sepsis(14) but markedly higher than published reports in critically ill patients without sepsis(15, 16), suggesting that dysregulated hemostasis and coagulation in severe COVID-19.

Notably, both VTE complications and major bleeding events occurred in critically ill patients. Hence, routine thromboprophylaxis was provided to critically ill patients based on an individual assessment of their thrombosis and bleeding risks in our study. For critically ill patients with extremely high levels of D-dimer and FDP associated with pulmonary microthrombosis, heparin was recommended. For those at a very high risk of bleeding, mechanical prophylaxis was instituted(17). For those used ECMO, better control of the aPTT (through better control of either coagulopathy or anticoagulation) was essential(18). This study has several limitations. First, a small population were included in this study. We hope that the findings presented here will encourage a larger cohort study. Second, among the 138 cases, some of the patients are still hospitalized at the time of manuscript submission. Therefore, it is difficult to assess the exact incidence of VTE and major bleeding events, and continued observations are needed. Third, this is a retrospective study. The data in this study permit a preliminary assessment of VTE and bleeding risk of patients with COVID-19. Further prospective studies need to determine the exact incidence of VTE among these patients and focus on thromboprophylaxis.

In conclusion, critically ill patients with COVID-19 suffered both high risk of thrombosis and bleeding risks. However, the prediction risk of VTE and major bleeding was low in non-critically patients. More effective VTE prevention strategies based on an individual assessment of bleeding risks were necessary for critically ill patients with COVID-19.
